

# INTRODUCTION

Acute myocardial infarction with ST-segment elevation is caused by the rupture or erosion of an atherosclerotic plaque, initiating intraluminal thrombosis resulting in partial or complete occlusion of a coronary artery. (*DeWood et al. 1980*), (*Falk et al. 1983*) & (*Davies et al. 1984*).

Primary percutaneous coronary intervention (PCI) is the preferred treatment for myocardial infarction with ST-segment elevation and is effective in opening the infarct-related artery. (*Zijlstra et al. 1999*), (*Keeley et al. 2003*), (*Silber et al. 2005*)

However, microvascular obstruction with diminished myocardial perfusion occurs in a large proportion of patients with a patent epicardial vessel after primary PCI, and this event is associated with an increased infarct size, reduced recovery of ventricular function, and increased mortality. (*Van 't Hof et al. 1998*), (*Van 't Hof et al. 1997*), (*Stone et al. 2002*), (*McLaughlin et al. 2004*), (*Poli et al. 2002*)

Microvascular obstruction is related to the embolization of plaque or thrombotic material downstream in the infarct-related artery. (*Topol et al. 2000*), (*Kotani et al. 2002*)

Embolization can occur spontaneously or by means of mechanical fragmentation during PCI. (*Topol et al. 2000*), (*Kotani et al. 2002*), (*Henriques et al. 2003*)

One coronary angiographic technique to assess the perfusion in the myocardial tissue is the myocardial blush grade. (*Van 't Hof et al. 1998*),(*Stone et al. 2002*),(*Poli et al. 2002*)

In clinical practice, electrocardiographic (ECG) analysis of the degree of resolution of ST-segment elevation after PCI is often used. (*Van 't Hof et al. 1997*),(*Poli et al. 2002*) & (*McLaughlin et al. 2004*).

The high frequency of suboptimal myocardial reperfusion after primary PCI has resulted in the development of various devices to protect the microcirculation. (*Napodano et al. 2003*)
